## ABSTRACT

LISA Pathfinder (LPF) was a technology pioneering mission designed to test key technologies required for gravitational wave detection in space. In the low frequency regime (milliHertz and below), where space-based gravitational wave observatories will operate, temperature fluctuations play a crucial role since they can couple into the interferometric measurement and the test masses' free-fall accuracy in many ways. A dedicated temperature measurement subsystem, with noise levels in  $10 \mu\text{K Hz}^{-1/2}$  down to 1 mHz was part of the diagnostics unit onboard LPF. In this paper we report on the temperature measurements throughout mission operations, characterize the thermal environment, estimate transfer functions between different locations, and report temperature stability (and its time evolution) at frequencies as low as  $10 \mu\text{Hz}$ , where typically values around  $1 \text{ K Hz}^{-1/2}$  were measured.

**Key words:** gravitational waves – space vehicles: instruments.

## 1 INTRODUCTION

LISA Pathfinder (LPF; Anza et al. 2005; Antonucci et al. 2012) was an ESA mission with NASA contributions designed to test key technologies for the future gravitational waves observatory in space, the Laser Interferometry Space Antenna (LISA; Amaro-Seoane et al. 2017). LPF was launched on 2015 December 3 and started

scientific operations at the Lagrange point L1 on 2016 March. The original mission plan included a 6 month operation period split between the two experiments onboard: the European LISA Technology Package (LTP) and the NASA Disturbance Reduction System (DRS). After an extended operations phase, the mission was finally decommissioned and passivated on 2017 July.

The main scientific goal of the mission was expressed in terms of a differential acceleration noise between two test masses in geodesic motion, i.e. in nominal free fall inside the spacecraft. LPF achieved residual acceleration noise levels of  $(1.74 \pm 0.01) \text{ fm s}^{-2}/\sqrt{\text{Hz}}$  above 2 mHz, and  $(60 \pm 10) \text{ fm s}^{-2}/\sqrt{\text{Hz}}$  at  $20 \mu\text{Hz}$  (Armano et al. 2016, 2018). Demonstrating this purity of free fall at these low

frequencies was well beyond the capabilities of any ground-based experiment.

Enabling a new observing window in the gravitational sky requires facing new technological challenges. The coupling of low-frequency temperature perturbations to instrument performance is one of these challenges. Indeed, temperature fluctuations will play an important role in space-borne gravitational detectors since typically their most significant contribution is in the low-frequency (sub-milliHertz) part of the measurement window where temperature driven effects may even limit the overall instrument sensitivity. Moreover, at such time-scales – temperature changes that can last for hours – they are ubiquitous to the satellite with a potential to impact different stages and subsystems of the measuring chain, e.g. thermal induced forces (Carbone et al. 2007) acting on the Gravitational Reference Sensor (GRS; Dolesi et al. 2003), temperature induced path-length variations (Nofrarias et al. 2007, 2013; Gibert et al. 2015) in the optical metrology subsystem (OMS; Heinzel et al. 2004) and thermal effects in all associated electronics.

Unlike most space missions, where the satellite house-keeping system is in charge of monitoring the environment, LPF included a precision diagnostics subsystem (Cañizares et al. 2009) designed with a two-fold objective. First, to monitor noise disturbances and, second, to study the contribution of these disturbances to the instrument noise budget. The diagnostic subsystem was composed of sensors (magnetometers, temperature sensors, and a particle counter) and actuators (heaters and coils). The latter were used to induce controlled perturbations, which allowed us to derive coupling factors and transfer functions between thermal and magnetic perturbations and the outputs of the GRS and the OMS.

In this paper we focus on the thermal environment during the LPF mission and report on the achieved onboard temperature stability. During periods of uninterrupted operation we see a temperature stability of tens of microKelvin in the milliHertz measuring band. We also identify the most significant drivers of thermal disturbances at milliHertz frequencies and suggest how these should be addressed in a future LISA mission. While the reported experiments were designed to answer questions for the LISA mission there is an increasing demand for very controlled and stable environments in a wide range of experiments, both on ground and in space, where these results will have a wider applicability. Examples include geodesy missions (Sheard et al. 2012), ongoing or proposed fundamental physics (Lämmerzahl et al. 2001; Aguilera et al. 2014) missions to on-ground experiments aiming at exoplanets detection (Stefansson et al. 2016). In all these cases temperature stability is crucial to suppress spurious effects arising from a large variety of thermal coupling phenomena.

The manuscript is organized as follows: in Section 2 we describe the temperature diagnostics items, their role and distribution in the instrument. Section 3 is devoted to the description of the temperature evolution during the mission timeline as measured by the diagnostics subsystem while Section 4 gives a more detailed insight in the noise performance and derives temperature couplings – transfer functions – between different sensitive locations in the instrument. We end with a final discussion where we provide our conclusion and implications for LISA.

## 2 THE THERMAL DIAGNOSTIC SUBSYSTEM

The temperature diagnostic subsystem onboard LPF was designed primarily to monitor temperature fluctuations in sensitive locations onboard the satellite. This section describes the elements composing the temperature diagnostics subsystem and their distribution in the

**Figure 1.** Distribution of temperature sensors in LPF. *Top:* Heaters and temperature sensors in the electrode housing (EH), the optical window (OW), and the optical bench (OB) from the diagnostics subsystems. *Middle:* Temperature sensors and heaters in the struts from the diagnostics subsystems. *Bottom:* Some of the platform sensors attached to thermal shield surrounding the instrument.

satellite. There are 24 thermal sensors and 18 heaters distributed around the LTP Core Assembly (Cañizares et al. 2009) as we show in Fig. 1. In the following section we summarize the main characteristics that describe this subsystem.

### 2.1 Sensors distribution and rationale

Temperature sensors were distributed across the instrument in order to monitor critical locations where temperature fluctuations could

perturb the main scientific measurement onboard, the differential acceleration between the two free-falling test masses. The distribution of temperature sensors in the instrument – see Fig. 1 – was chosen to study the effects that can produce such perturbations. These were basically divided in two families: (i) thermal induced forces directly applied on the test masses and (ii) thermoelastic distortions of the optical system.

The first kind of effect is highly dependent on the gradient of temperature across the GRS housing, hence two temperature sensors were attached on both sides of the sensitive axis (the axis that joins both test masses) of the electrode housing (EH) containing the test masses. The main instrument, consisting of both the test masses inside the vacuum enclosure and the optical bench (OB), was hosted inside a thermal shield to protect it from the fluctuations associated with the electronic boxes. The struts holding the instrument inside the thermal shield were the thermal link to the outer environment and therefore temperature was monitored in six of them, from a total of eight. Three sensors were attached to each of the two optical windows (OWs), the optical elements enabling the laser link between the OB and the test masses. Finally, four temperature sensors were located on the OB, one on each corner, to monitor gradients which could potentially induce thermoelastic induced bending.

The satellite also included sensors monitoring temperature for each of the different units in the platform. These were located outside the thermal shield containing the instrument and, were primarily for monitoring unit health so had less stringent requirement in terms of precision or stability than the sensors of the temperature diagnostics subsystem. They are however indicative of the temperature fluctuations of the electronic units and, hence, useful as a reference of the temperature environment surrounding our instrument.

## 2.2 Electronics and sensor performance

On-ground estimates of the effects which can potentially disturb the main free-fall measurement set a requirement for temperature stability of  $100 \mu\text{K}/\sqrt{\text{Hz}}$  in the LPF measuring bandwidth,  $1 \text{ MHz} \leq f \leq 30 \text{ MHz}$ . In the design phase of the instrument it was decided that the temperature measurement subsystem had to be able to clearly distinguish such levels of disturbances and therefore the thermal sensitivity requirement was set to  $10 \mu\text{K}/\sqrt{\text{Hz}}$  in the same measurement band (Lobo et al. 2006).

The sensors selected to achieve this goal were Negative Temperature Coefficient (NTC) thermistors (Betatherm G10K4D372) with a nominal resistance of  $10 \text{ k}\Omega$ . These were considered to be the best candidate to achieve the demanding requirements (Sanjuán et al. 2007). On the downside, the oxides used to manufacture thermistors contain magnetically active materials. This can have a potential impact when used in locations close to the test mass as they can introduce a source of local magnetic gradient. The studies performed showed, however, that the potential impact of this effect was substantially reduced by means of demagnetization procedures and hence was estimated to not impact the instrument performance (Sanjuán et al. 2008).

The front-end electronics was based on an AC powered Wheatstone bridge (Sanjuán et al. 2007). A constraint to be taken into account in the design of the subsystem was the dissipated power in the temperature sensors: it was limited to  $10 \mu\text{W}$  in order to prevent both, thermal effects appearing in critical subsystems to which the sensors were attached, and to avoid self-heating errors in the sensor. In order to improve the resolution, six scales were defined with centre temperatures 12, 15, 20, 22.5, 25, and  $27.5^\circ\text{C}$

which, at the same time, kept the output voltage of the bridge close to zero. Change in temperature scales produced spikes in the read-out as a consequence of the different zero in each temperature scale. These spikes only appeared during phases of high temperature drifts, for example temperature experiments or changes in the spacecraft configuration, and never during phases of scientific runs where the instrument was kept unperturbed to achieve the highest degree of free fall. The spikes were suppressed from the time series by means of data analysis post-processing.

As commented above, the temperature diagnostics subsystem included heaters with the aim of injecting controlled temperature perturbations in sensitive locations and study their coupling to instrument performance. Two different types of heaters were used: Kapton heaters ( $45 \Omega$  resistors) with a maximum power of  $2 \text{ W}$  were attached to the lateral sides of the OWs and in the struts whilst the heaters inside the EH were thermistors ( $2 \text{ k}\Omega$  resistors) acting as heaters, with a maximum power of  $45 \text{ mW}$ . The decision to use the latter was driven by the stringent contamination requirements inside the EH.

## 3 TEMPERATURE EVOLUTION DURING OPERATIONS

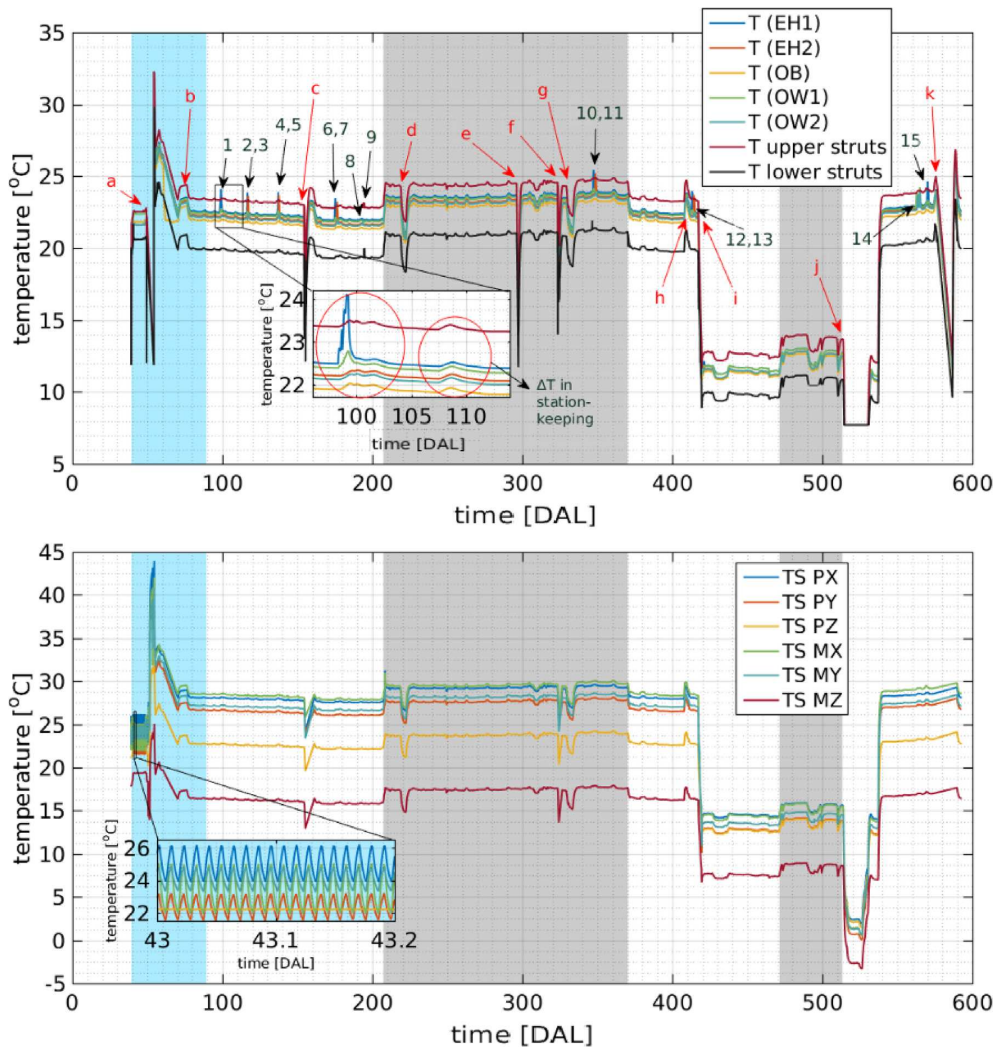

LPF was launched from the French Guiana on 2015 December 3. It took approximately a month – including LEOP (Launch and Early Orbit/Operations Phase) and apogee increase manoeuvres – to reach the L1 orbit and start commissioning phase. LTP commissioning started on 2016 January 11 and lasted until March 1st, when the mission started operations phase. LPF underwent different phases during scientific operations which included nominal operations for the two experiments onboard, the LTP and the DRS, and an extended period of operations for both of them. Fig. 2 shows the temperature as measured during all the mission by the diagnostics subsystem thermistors located on the LTP (top panel) and by the platform sensors attached to the external face of the thermal shield surrounding the LTP instrument (bottom panel). In the current section we provide some insight on the operations timeline from the point of view of the temperature evolution in the satellite as provided by the previously described sensors.

### 3.1 Commissioning

The commissioning was a particularly active period in terms of temperature variations. It started during the first days of 2016 January, after a cruise phase to L1. The first set of operations relevant from the temperature point of view was the *bang-bang* temperature control active during the first days of operations. As seen in the inset of the Fig. 2 lower panel, it produced  $\sim 2^\circ\text{C}$  peak-to-peak variations with a frequency around  $1 \text{ MHz}$  as measured by the platform sensors which was also measured, after the thermal shield attenuation, by the higher precision diagnostics sensors inside. As we will show in Section 4.2 this allows an experimental determination of the thermal shield thermal transfer function.

After this first phase and once in the desired orbit around L1, the propulsion module was ejected. This corresponds to the data gap in the commissioning phase – see the marked event in Fig. 2 – since the LTP instrument was switched off during this action. The sudden temperature increase afterwards is an intended heating of the instrument to increase the out-gassing rate and improve the cleanliness conditions before the release of the test mass and the start of free-fall operations. The release of the test masses took place on February 15th and 16th and it appears in the temperature

**Figure 2.** Temperature evolution during the whole mission timeline. The time axis is Days After Launch (DAL). The initial cyan area (DAL 40-90) corresponds to the commissioning. The two grey shaded areas (DAL 210-370 and 470-510) correspond to the DRS operations, and the rest are LTP operations. *Top:* Temperature as measured by the diagnostics subsystem located in sensitive location of the LTP instruments, namely the OW, the OB, the EH, and the struts holding the LTP inside the thermal shield. The traces show the average temperature in locations with more than one sensor (four in the EH and three in the OW) *Bottom:* Temperature evolution during the whole mission timeline as measured by the platform sensors attached to the outer face of the thermal shield surrounding the LTP.

read-out as a temperature increase due to associated satellite operations.

### 3.2 LTP operations

The two periods of LTP operations took place from 2016 March 1 to 2016 June 26 in its nominal phase and from 2016 December 8 to 2017 March 17 and 2017 May 1 to 2017 June 30 in its extended phase. In Fig. 2 we show the temperature evolution as measured by the temperature diagnostics subsystem. A first characteristic to notice from this is a constant  $3.5^{\circ}\text{C}$  gradient between the upper and lower struts during the whole mission, which only goes below the  $3^{\circ}\text{C}$  during the cool down phase that we explain below. A much lower temperature difference is also observed between the temperature sensors located in the rest of LTP locations. In analysing these, it must be taken into account that the temperature sensors of the LTP diagnostics subsystem were optimized for precision and not for accuracy, showing typically an absolute uncertainty  $\sim 0.2^{\circ}\text{C}$ .

Therefore the differences in absolute temperature below this value must be considered within the error of the temperature read-out.

The temperature evolution during the LTP operations phase shows a series of sudden decreases of temperature together with some other, smaller, temperature increases. In Table 1 we gather the main features that caused the temperature decreases in the timeline. Most of these correspond to pauses in normal satellite operations, for example anomalies of the thrusters subsystem during DRS operations or reboots of the Data Management Unit (DMU) – the computer of the LTP instrument – in the LTP phase operations. These events can trigger the satellite safe mode, which switches off of some electronic units onboard, causing a consequent change in the satellite thermal balance.

The period of operations at lower temperature starting 430 DAL corresponds to an intended cooling down of the spacecraft with the objective of studying the instrument performance at a different temperature working point. The series of measurements that took place during these weeks could successfully determine a decrease

(15) Thermal injections in EH1	24 Jun '17 (569)

in the instrument acceleration floor noise due to a suppression of the Brownian noise contribution due to gas particles hitting the test masses (Armano et al. 2018). There were two cooling down phases – see the dates in Table 1. The first one decreased the temperature  $\sim 10^\circ\text{C}$  leaving the housing surrounding the test masses at  $\sim 12^\circ\text{C}$ . The second cooling down went below the design range of the temperature diagnostics subsystem and therefore appears as a saturated line in the temperature read-out in the upper panel of Fig. 2. The lower panel in the same figure shows however the temperature in the thermal shield and how the coolest sensor in this structure reached  $\sim -3^\circ\text{C}$ . Given the complete time series and from the surrounding temperatures, we can estimate a temperature in the test mass EH in the housing for this period  $\sim 2^\circ\text{C}$ .

The LPF operations timeline was planned to get the maximum scientific yield from its capabilities as technology demonstrator. As such, an important fraction of the operations time was dedicated to experiments to gain insight in the different mechanism that can perturb the free fall. Temperature fluctuations were a relevant part of the noise budget and, hence, several experiments were planned during the mission duration. Table 2 shows the list of executed experiments in the different locations where the instrument included heaters from the diagnostics subsystem, as we have previously described in Section 2.2. These experiments – with temperature increases  $\sim 2^\circ\text{C}$  and some of them lasting days – had an important impact in the temperature profile and for that reason were carefully

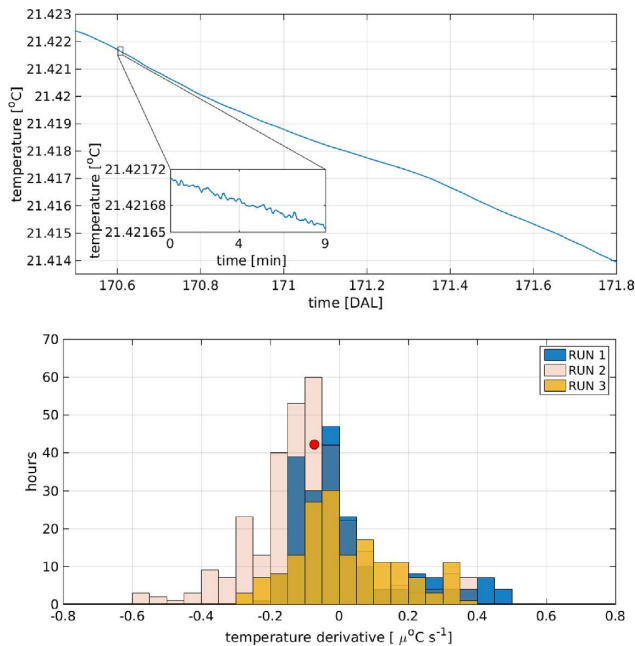

planned in advance. The typical impact is shown in the inset of the top panel of Fig. 2. The increase in temperature when injecting thermal signals in one EH is  $\sim 2^\circ\text{C}$  for the sensors located on the same EH and  $\sim 0.1^\circ\text{C}$  for the sensor on the other EH,  $\sim 0.2^\circ\text{C}$  for the sensors on the OB,  $\sim 0.4^\circ\text{C}$  for the sensors on the nearest OW, and  $\sim 0.15^\circ\text{C}$  on the farther OW. In comparison, heaters located on the OWs and struts produced a temperature increase of  $\sim 1^\circ\text{C}$ , as measured by temperature sensors on these locations.

For the particular case shown in Fig. 2 a series of temperature modulations were applied to the EH producing a modulating force in the test mass that was used to derive the amount of coupling of the thermal-induced forces in the test mass motion. The modulation pattern was repeated at different absolute temperatures – increasing the applied DC power – producing a stair-like profile. The total experiment duration was about a day and it took LTP 2–3 d to recover from this disturbance. In Section 4.2 we will come back to these injections to quantitatively characterize these thermal links.

The metastable orbit in L1 forced periodic station-keeping manoeuvres to keep the satellite in the predetermined orbit. Once the propulsion module was jettisoned – during the commissioning phase – the microNewton propulsion subsystem was the only available thrusting system in LPF. The low thrust available required prolonged operations of the thrusters, initially set to one 12 h period each week. In thermal terms, the result of this operation is shown again in the inset of the top panel of Fig. 2, i.e. the operation of the thruster subsystem in wide range mode (with less precision but higher thrust) for station keeping turned into a  $\sim 0.1^\circ\text{C}$  homogeneous increase in the different locations of the satellite. Although not representing an operational inconvenience, this mode of operations resulted in a reduction of the mission effective duty cycle since the scientific runs required an extremely quiet environment. Hence, the scientific runs duration were limited by the long time-scales needed for the thermal environment to recover the steady state after station keeping. Later in the mission, this limitation was overcome by allowing longer, less frequent station keepings. That way, week-long scientific runs were executed which allowed the estimation of the instrument acceleration noise down to the  $20\ \mu\text{Hz}$  regime (Armano et al. 2018). This is an important lesson for LISA as we point out in our final section. We can also see a thermal gradient between the temperatures measured by the sensors located on the LCA, with a maximum gradient of  $\sim 13^\circ\text{C}$ , as shown Fig. 2 (bottom). During the first cooling down, the lower temperature given by the sensor TS MZ reaches a temperature of  $\sim 7^\circ\text{C}$ , while during the second cooling down it reaches a negative value,  $\sim -3^\circ\text{C}$ , the only temperature registered below zero.

### 3.3 DRS operations

DRS operations took place from 2016 June 27 to 2016 December 7 in its nominal phase and from 2017 March 18 to 2017 April 30 in its extended phase. The hand over to the DRS team required a series of configuration changes which had an impact on the thermal environment. As thoroughly described in Anderson et al. (2018), the hand over to the DRS team implied that, while the LTP instrument was still providing measurements of Spacecraft and test masses attitude, this information was sent to the Integrated Avionics Unit (IAU), which determined the forces and torques to be applied to the test masses and to the Spacecraft. The first were delivered again to the LTP while the second were sent to the two Colloidal MicroNewton Thrusters Assemblies (CMTAs). Both IAU and CMTAs were inactive during LTP operations.

**Figure 3.** *Top:* Typical temperature evolution of a sensor located in the OB (TS13) during a quiet noise run. *Bottom:* Histogram showing the number of hours with a given temperature drift for a sensor in the OB (TS13) for three different noise runs: RUN 1 from November 17 to November 26 (2016), RUN 2 from February 14 to February 27 (2017) and RUN 3 from May 29 to June 5 (2017). The dot indicates the temperature derivative that corresponds to the time series in the top plot.

As seen in Fig. 2, the continuous operations of these two units (grey shaded areas) changed the thermal balance in the satellite, raising the overall temperature by  $\sim 2^\circ\text{C}$  with respect to the LTP operations. The DRS operations phase shows some pronounced decays in temperature corresponding with short interruptions of operations due to detected anomalies in the thruster subsystem. The reader is referred to Anderson et al. (2018) for more detail on these.

#### 4 TEMPERATURE STABILITY IN LISA PATHFINDER

Achieving the scientific goal in LPF is a complex endeavour that requires excellent design and performance of several sensors and actuators. Temperature stability is a crucial one among them since it can impact in several ways the measurement chain, as we have previously described. The aim of the current section is to quantitatively assess the temperature stability of our instrument which, as we will see, goes in parallel with the determination of the performance of our temperature diagnostics subsystem.

In Fig. 3 we evaluate the typical stability measured in LPF during a scientific run. We use a sensor in the OB to show the typical evolution of the temperature during a quiet interval. To give a more comprehensive view we include in the bottom panel of Fig. 3 an histogram with the temperature derivative for a sensor in the OB during three noise runs. Overall, the instrument spent nearly 250 d with temperature drifts in the range  $\pm 1 \mu^\circ\text{C s}^{-1}$ . Temperature drifts are not only an important figure for the platform stability but, as we comment below, they have an important role in the evaluation of the performance of our sensors.

#### 4.1 Temperature fluctuations amplitude spectral density

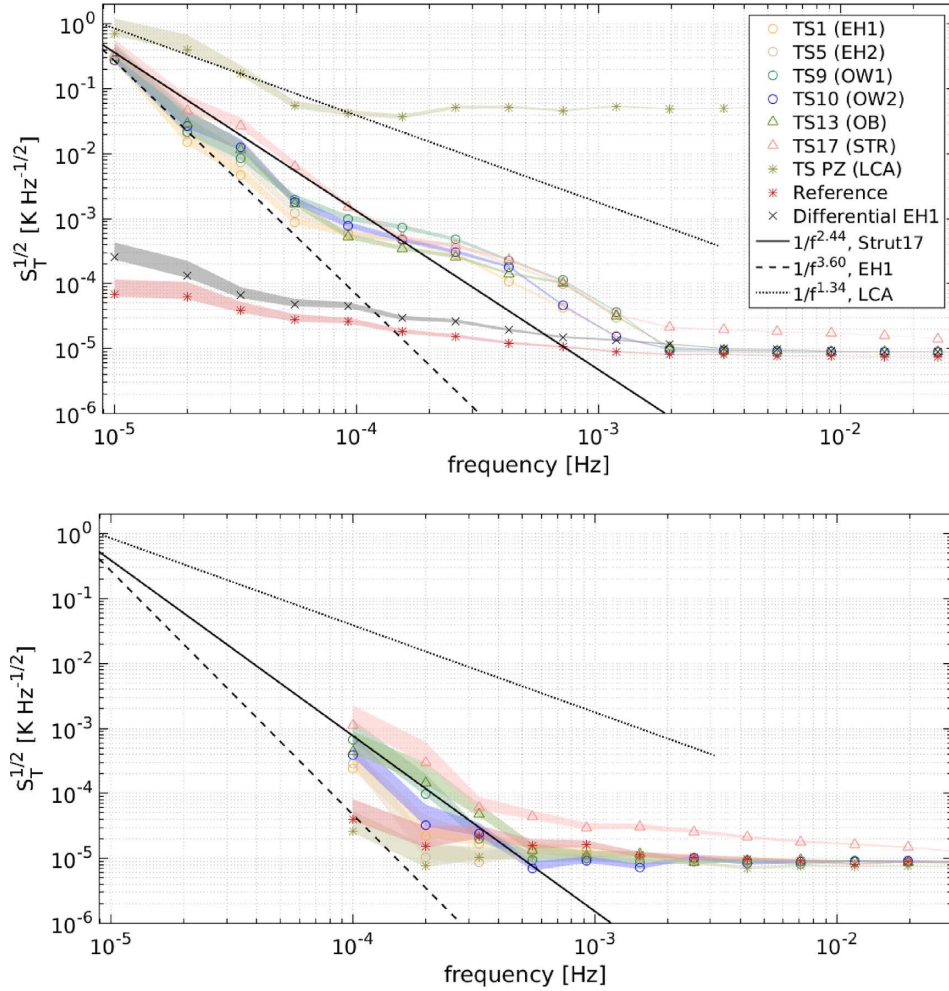

In order to evaluate the temperature stability in the instrument we start evaluating the stability of the environment surrounding the instrument. As previously described, the LTP was encapsulated in a thermal shield to suppress temperature fluctuations arising in the electronics surrounding the experiment. A series of sensors – not belonging to the diagnostics subsystems – monitored the temperature fluctuations at various locations around the satellite. These sensors were not designed for precise measurements of temperature stability, and therefore their noise floor,  $50 \text{ mK}/\sqrt{\text{Hz}}$ , is orders of magnitude above the ones belonging to the diagnostics subsystem. Despite its reduced precision, the temperature fluctuations of the spacecraft are high enough at low frequencies to measure them.

To evaluate temperature fluctuations we compute the amplitude spectral density – the square root of the power spectral density – by means of the Welch averaged periodogram. We use segments of 400 000 s and apply Blackman–Harris window to prevent spectral leakage. To make sure that the window is not biasing our estimate we get rid of the lowest four frequency bins of the spectra. With the remaining spectra we evaluate the power at low frequency by means of a power-law fit at the four lowest frequency bins. In the locations where we have more than one sensor we use an average of sensors when considering the power-law fit. For the struts, where each sensor is attached to a different strut, we use the TS17 sensor as a typical case to evaluate the low-frequency power. For the interested reader we provide the coefficients of the fit obtained in each individual location in Appendix A.

In Fig. 4 we show our results for a long stable run on 2017 February. In the top panel we can distinguish a thermally induced  $f^{-1.34 \pm 0.05}$  power law below  $100 \mu\text{Hz}$  in all the six sensors attached to the thermal shield. These low-frequency fluctuations are transmitted to the instrument through the thermal shield and the struts. As the spacecraft-induced temperature fluctuations leak into the instrument they are successively suppressed, since each stage acts as a thermal low-pass filter. This can be appreciated when comparing the different slopes of the power-law fits in Fig. 4. We notice how low-frequency power has decreased from the original  $f^{-1.34 \pm 0.05}$  on the outer layer of the thermal shield to  $f^{-2.44 \pm 0.06}$  in the struts and even further to  $f^{-3.60 \pm 0.04}$  if we continue to the EH sensors. The cause of the decrease in power at lower frequencies is, as previously said, the different layers of materials that the heat flow need to cross, which act as a series of consecutive thermal low-pass filters. In Section 4 we will quantify and model this behaviour.

So far our analysis focused on the 2017 February science run. However, in order to evaluate the non-stationarities in temperature fluctuations we compared these results to the rest of science runs where the instrument was kept unperturbed in its most sensitive configuration for several days. Since we are purely interested in the temperature contribution, for each of these we compute the amplitude spectral density in the  $10\text{--}30 \mu\text{Hz}$  band. Results are shown in Fig. 5. The amplitude of temperature fluctuations in the lowest bins of the LISA frequency band is maintained in the  $50\text{--}100 \text{ mK}/\sqrt{\text{Hz}}$  range for most of the runs in the OB, OW, and EH locations. As expected, the amplitude spectral density can increase up to  $180 \text{ mK}/\sqrt{\text{Hz}}$  in some runs for the temperature in the struts as shown in the lower panel of Fig. 5. The analysis shows therefore a considerable level of stationarity in the amplitude of temperature fluctuations in the  $10\text{--}30 \mu\text{Hz}$  band for the whole duration of the mission. The same conclusion could be drawn by comparing the power-law fits for each of the runs we have analysed. We refer to the interested reader to Appendix A, where we provide a table with

**Figure 4.** Temperature stability measured as amplitude spectral density in different locations in LTP during the period 2017 February 14–27. *Top:* Different locations inside LTP as measured by the temperature diagnostics subsystem. When different sensors were available we use the mean value of the measurements to obtain the fit at low frequencies. In addition, we show the temperature given by one spacecraft temperature sensor in the outer face of the instrument thermal shield, also showing the fit for low frequencies taking into account the mean value of the measurements given by all the sensors located on the shield. We also show differential and reference measurements. *Bottom:* The same as before evaluated in a shorter segment (2017 February 19–20) with lower temperature drift.

the fits to power laws for each of these runs together with its dates of occurrence.

Temperature fluctuations in these locations are hence described by the power-law fits shown in Fig. 4. The rest of features appearing in the plot do not describe temperature fluctuations but are instead related to our temperature read-out. At higher frequencies the LPF temperature front end is limited by read-out noise, which is fundamentally dominated by the Wheatstone bridge noise. The in-flight measurements reached the design limit of  $10 \mu\text{K}/\sqrt{\text{Hz}}$ , a level that was also achieved during on-ground testing (Lobo et al. 2006; Sanjuán et al. 2007). This noise floor goes down to nearly 1 mHz which was the LPF measuring bandwidth.

The frequency regime spanning  $0.2 < f < 2 \text{ mHz}$  is dominated by read-out noise arising from non-linearities in the temperature diagnostics ADC (Sanjuán, Lobo & Ramos-Castro 2009). Although being studied and characterized during the design phase, this read-out noise source was not considered critical for the mission success since it was limited to frequencies below the LPF band. This contribution can be modelled and subtracted to some extent (Sanjuán & Nofrarias 2018). Nevertheless the design of the future LISA temperature diagnostics subsystem will need to overcome this noise

source that otherwise would affect the discrimination of temperature induced disturbances in the sub-milliHertz band. Since the ADC-induced noise increases with wider excursion in the ADC range, a segment that explores less range will show a reduced impact of such a noise. The bottom plot in Fig. 4 confirms this by evaluating the amplitude spectral density of temperature fluctuations in a shorter segment with less temperature drift.

Apart from the absolute temperature measurements, the temperature diagnostics front end included some other channels to help disentangle noise sources in the actual temperature read-out. On one side, the so-called *reference* measurements were used to unambiguously determine the noise floor of the read-out. These measurements were obtained by means of high stability resistors mounted on the same Wheatstone bridge used for the temperature sensing, allowing a direct measurement of the bridge electronics noise. On the other side, for some designated couple of sensors the electronics implemented a direct differential measurement by comparing directly them in the Wheatstone bridge, that is a direct hardware differential measurement. These were called *differential* measurements. Both are shown in Fig. 4. The differential measurements are, in particular, a second cross-check to confirm the

**Figure 5.** Time evolution for the amplitude spectra of temperature fluctuations in the 10–30  $\mu\text{Hz}$  frequency range. Only noise runs with several days of stable conditions. In grey we show the temperature profile of the mission for comparison. *Top*: OB, OW, and EH sensors. *Bottom*: temperature sensors at the struts.

non-thermal origin of the excess noise observed in the mid-band. Indeed, due to its nature the differential measurements are closer to zero and, hence, use less range of the ADC. As a consequence they are less exposed to ADC non-linearities induced noise, as it is shown in the plots.

#### 4.2 Thermal transfer functions

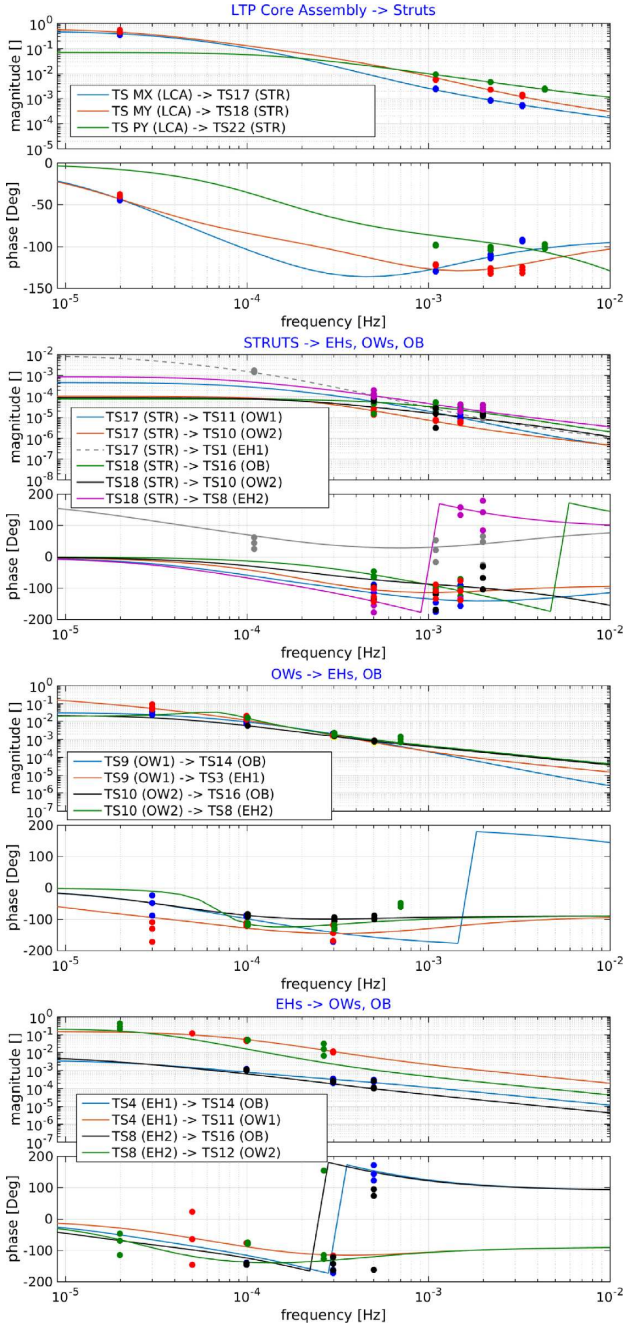

In the last section we evaluated the behaviour of temperature fluctuations and quantified the noise spectra at different locations and its temporal evolution. In the following we study the correlation between temperature fluctuations at different locations. This is an important exercise to understand the thermal link between the different subsystems onboard, a key aspect for an instrument like LPF and LISA. We recall that the temperature diagnostic subsystem onboard included heaters in thermally sensitive locations such as the EH, the OWs, and the struts. The objective of injecting temperature pulses at these locations was to study the instrument response to thermal disturbances in terms of forces exerted on the test mass or displacements measured by the optical read-out. The results of these experiments are of interest for the design of the future LISA mission and will be published elsewhere. However, as a side product, we can experimentally derive thermal transfer function between different locations, as we show below.

To do so we use the different heat pulses that were injected in the different locations during the mission timeline. The list

of experiments is given in Table 2 together with these, we will make use of the temperature *bang–bang* control phase during the commissioning – with temperature variations  $\sim 2^\circ\text{C}$  – produced by platform heaters. While the former will characterize point-to-point correlations between locations inside the experiment, the latter will tell us about the response of the diagnostic subsystem sensors to external perturbations, a characterization that can be of interest for the future LISA mission.

For each of these phases where an active thermal stimulus was present in the satellite, we derive the transfer functions comparing the Discrete Fourier Transform (DFT) of the temperature time series at two different locations. The result of this operation is a complex value that we show, expressed as magnitude and phase, by the dots in Fig. 6. The lines in the same plot correspond to the best-fitting models in frequency domain. In Appendix B we detail the estimation and modelling of the transfer functions and provide the parameters describing the models obtained during the analysis. It is important to keep in mind when interpreting these results that thermal injections were not intended for the purpose of this study and therefore neither the amplitude nor the frequency of the applied signal are the optimal ones.

Fig. 6 summarizes our results. We show in the different panels the thermal transfer functions for each different location where the stimulus was applied. The top panel describes the effect of the thermal shield surrounding the main instrument onboard. We notice that the attenuation of temperature fluctuations from the external en-

**Figure 6.** Transfer functions between sensors in different locations. The points show these transfer functions at a certain frequency while the lines represent the fit to these functions.

vironment to the LPF instrument is better than  $10^{-2}$  for fluctuations with frequencies above 1 mHz. Temperature fluctuations are then further attenuated on their way to the inner part of the instrument when crossing the struts holding the instrument inside the thermal shield. Indeed, the second panel shows the temperature suppression factor from the different struts to the rest of the locations in the inner core of the instrument. Any temperature fluctuation moving through this path in milliHertz equivalent time-scales is attenuated by  $5 \times 10^{-5}$ . In this case, the CFRP (Carbon Fiber Reinforced Polymer) struts and the massive OB Zerodur structure are acting as equivalent thermal low-pass filters.

The last two panels describe the impact of thermal experiments – as measured by surrounding sensors – in the inner core of the instrument, i.e. the OW and the EH, respectively. A first point to take into account in understanding these figures is that, while the experiments in the OW reached temperature increases of  $\sim 2^\circ\text{C}$ , the temperature modulations in the EH – being this a much more thermal sensitive locations – were instead in the milliKelvin range. Consequently, the temperature increases due to the EH experiments in the surrounding sensors are not so clearly measured and, thus, these transfer functions are measured with lower precision. Even though, thanks to the high precision of the temperature sensors we are able to estimate a  $10^{-4}$  attenuation in the LPF measuring band for temperature fluctuations being transferred from the EH to the OB. The time-scales characterizing the thermal path for these fluctuations is  $\sim 2$  d which makes easier to distinguish from other decorrelated temperature fluctuations.

Although not shown in the figures, we can get an estimate of the thermal transfer function at even lower frequencies. When taking into account the complete temperature series we observe a year modulation of the spacecraft solar array temperature of  $\sim 3.5^\circ\text{C}$ , which is proportional to the variation of the spacecraft solid angle with respect to the Sun throughout this period. The same modulation can be traced to the EH with an amplitude of  $\sim 0.35^\circ\text{C}$ , from where we derive a factor 10 attenuation to external temperature fluctuations in the frequency  $3 \times 10^{-8}$  Hz, that is to say a year period.

## 5 CONCLUSIONS AND IMPLICATIONS FOR LISA

The temperature diagnostics was a key subsystem of the LPF mission and was designed to disentangle the contribution of temperature fluctuations from the main metrology and force measurements. The temperature diagnostics subsystem consisted of 24 thermistors attached to sensitive locations and 16 heaters to produce controlled inputs to calibrate the experiment response. The subsystem operated throughout the full mission duration, from the commissioning phase on 2016 January to the mission passivation on 2017 July. The sensors distributed across the LPF instrument allowed a precise characterization of the temperature variations throughout the mission and helped identify noise disturbances in the otherwise extremely stable environment in the satellite. We have detailed the reasons – either intended or accidental – of temperature variation in the mission timeline.

Looking towards LISA, the most evident lesson learnt from the LPF operations refers to the station-keeping manoeuvres. These were mandatory to keep the satellite in the Lissajous orbit in L1. However, the low thrust available in the propulsion system forced a several hours manoeuvre that produced an overall  $\sim 100$  mK temperature increase. Originally, this operation was repeated each weekend which, after the long thermal transient, left a few days for science runs in stable conditions. This periodic station keeping is ruled out for LISA given that it would seriously impact its performance in the low frequency regime. Each LISA spacecraft will be injected in its individual orbit avoiding the need of periodic corrections. Other temperature perturbations, like the thermal experiments that were repeated frequently in a technology demonstrator as LPF will be kept to the commissioning phase for LISA.

In terms of performance, the diagnostic subsystem achieved the required performance of  $10 \mu\text{K}/\sqrt{\text{Hz}}$  in the mission band,  $1 \text{ mHz} < f < 30 \text{ mHz}$ , showing only a slight deviation in the lowest frequency bin. The latter is due to a coupling of the temperature drift onboard with non-linearities in the ADC. The effect was already known

to affect the sub-milliHertz band during the design phase but the extensive operation period in an extremely quiet environment has allowed a precise characterization. This will allow an improved design overcoming this read-out noise contribution for the future LISA temperature diagnostics subsystem.

The low-frequency band below the 100  $\mu\text{Hz}$  is dominated by temperature fluctuations that, in this band, exceed the noise contribution from the ADC non-linearities. Thanks to the extensive data set we have been able to determine a noise level of 50–100  $\text{mK}/\sqrt{\text{Hz}}$  in the lowest bins of the LISA frequency band, 10–30  $\mu\text{Hz}$ , for those locations in the inner core of the experiment. This noise level was maintained during the different science runs throughout the mission, which provides an important insight of the stationarity of the temperature fluctuations in the very low frequency domain during flight operations.

We have also determined a  $f^{-3.60 \pm 0.04}$  power law for the temperature fluctuations in the EH dominating the lowest frequency bins, below the 100  $\mu\text{Hz}$ . The cause of these fluctuations must be sought in the electronic units surrounding the main instrument in the satellite. We have also determined fluctuations outside the thermal shield to be characterized by a  $f^{-1.34 \pm 0.05}$  power law. The characterization of these low-frequency temperature fluctuations is relevant for LISA since this corresponds to the lowest frequency bins of the mission, where temperature variations are expected to provide a significant limit to the instrument's performance.

These figures are however not directly applicable to LISA, being the mission still in its definition phase, but they are an important asset since they serve as an anchoring point for thermal design. In the same line of paving the way for the thermal design of the future LISA mission, we took advantage of the different thermal experiments in the mission timeline to determine the thermal transfer function between locations, thereby deriving the attenuation factors due to the different shielding layers that can be used as guidance for the future LISA design.

## ACKNOWLEDGEMENTS

This work has been made possible by the LISA Pathfinder mission, which is part of the space-science program of the European Space Agency. The French contribution has been supported by CNES (Accord Specific de projet CNES 1316634/CNRS 103747), the CNRS, the Observatoire de Paris and the University Paris-Diderot. EP and HI would also like to acknowledge the financial support of the UnivEarthS Labex program at Sorbonne Paris Cité (ANR-10-LABX-0023 and ANR-11-IDEX-0005-02). The Albert-Einstein-Institut acknowledges the support of the German Space Agency, DLR. The work is supported by the Federal Ministry for Economic Affairs and Energy based on a resolution of the German Bundestag (FKZ 500Q0501 and FKZ 500Q1601). The Italian contribution has been supported by Agenzia Spaziale Italiana and Istituto Nazionale di Fisica Nucleare. The Spanish contribution has been supported by Contracts No. AYA2010-15709 (Ministerio de Ciencia, Innovación y Universidades, MICINN), No. ESP2013-47637-P, and No. ESP2015-67234-P (MINECO). ## APPENDIX A: LOW-FREQUENCY TEMPERATURE POWER-LAW FITS

We compute the amplitude spectral density by means of the Welch averaged periodogram. We use segments of 400 000 s and apply Blackman–Harris window to prevent from spectral leakage. After subtracting the lowest four frequency bins, we perform a power-law fit at the (remaining) four lowest frequency bins.

The expression we use for the fit is given by

$$S^{1/2}(f) = b \times (2\pi f)^k \quad (\text{A1})$$

where  $S^{1/2}(f)$  is the amplitude spectral density and  $b$  and  $k$  are the parameters of the fit. In the locations where there is more than one sensor we use an average of sensors when considering the power-law fit, these are the electrode housing (EH1 and EH2) with four sensors in each of them; the optical windows (OW1 and OW2) with three sensors in each; and the optical bench (OB) with four sensors, one in each corner. The six remaining (TS17–TS22) correspond to sensors attached to different struts. We recall that only six out of the eight struts had a pair heater/sensor attached.

In Table A1 we provide the results of the fits for each of the noise runs during the LTP operations phase. These were periods where the instruments was configured in its optimal sensitivity configuration and left unperturbed during days and even weeks in some cases. For the sake of completeness we list here below the periods where these runs took place.

**Table A1.** Parameters for the power-law fit of the temperature fluctuations amplitude spectral density at low frequencies. The model is given in equation (A1) and the different runs described in the text.

The results of the power-law fits in Table A1 support the ones previously showed in Fig. 5. In that case, we provided the time evolution for the amplitude spectra of temperature fluctuations in

the 10–30  $\mu\text{Hz}$  frequency range for the same noise runs. We consider both, the power-law fit and the noise density in the low frequency regime, providing a complementary view of the same phenomena, which can be of interest for the reader.

## APPENDIX B: THERMAL TRANSFER FUNCTIONS

The thermal transfer function between an origin location A and a final location B at a given frequency  $f$  is experimentally computed

**Table B1.** Thermal transfer functions parameters between different locations. The model is given in equation (B2).

Origin $\rightarrow$ End	$r_1$	$p_1$	$r_2$	$p_2$	Corner frequency ( $\mu\text{Hz}$ )	DC gain

TS8 $\rightarrow$ TS16	$-7 \times 10^{-7}$	$-1 \times 10^{-3}$	$5 \times 10^{-7}$	$-7 \times 10^{-5}$	23	$6.4 \times 10^{-3}$
TS8 $\rightarrow$ TS12	$-2 \times 10^{-5}$	$-1 \times 10^{-3}$	$4 \times 10^{-5}$	$-9 \times 10^{-5}$	26	$4.2 \times 10^{-1}$

as

$$H_{A \rightarrow B}(f) = \frac{\tilde{T}_B(f)}{\tilde{T}_A(f)} \quad (\text{B1})$$

where  $\tilde{T}_A(f)$  and  $\tilde{T}_B(f)$  are the DFT of the temperatures at the location A and B at a given frequency  $f$ . Transfer functions are thus only computed between locations linked with pairs of sensors. In order to be representative of the heat flow between locations, these are just estimated when a heat input is active at the origin location, in which case we can make use of the temperature sensor close to the heater as representative of the heat injection. As previously commented, the transfer functions from the outside of the thermal shield to the inside are derived using the characterization provided by the *bang–bang* controller during the commissioning. These was a homogeneous temperature modulation of all the spacecraft from where we can extract thermal transfer functions from a temperature sensor outside the thermal shield to its closest counterpart inside, typically attached to a strut.

Once we have derived the points that experimentally define the transfer function, we can fit them to a continuous model given by

$$H_{A \rightarrow B}(s) = \frac{r_1}{s - p_1} + \frac{r_2}{s - p_2} \quad (\text{B2})$$

where  $H_{A \rightarrow B}(s)$  is the Laplace transform of the differential equation that describes the heat flow between points A and B. In our case, a second-order transfer function model described by residuals,  $r_1$  and  $r_2$ , and poles,  $p_1$  and  $p_2$ . This expression corresponds to a differential equation that can be understood as an approximation to second order of the heat flow equation that describes the heat flow from the origin to the final location. The fit is done using the vector fit algorithm (Gustavsen & Semlyen 1999) implemented in the LTPDA toolbox (Hewitson et al. 2009). In Table B1 we report the values obtained for these fits and in Fig. 6 we show a representative set of these types of transfer functions.
